Abstract—P2P systems have emerged as a promising technology to support the dissemination of information on the Internet, including multimedia streams with quality of service requirements. This work presents Thicket, a protocol for building and maintaining multiple spanning trees over an overlay network, providing a dissemination scheme that promotes load distribution across all participants and fault-tolerance. The proposed design was evaluated using simulations and a prototype implemented in Java. The Peersim was used to simulate a network composed of 10,000 nodes and the prototype was tested on the PlanetLab infrastructure.

I. INTRODUCTION

Mechanisms to support the dissemination of information in a reliable and efficient manner, to a very large number of participants, are extremely relevant for a wide range of applications, ranging from large scale monitoring and control infrastructures [1] to live video streaming and IP Television (IPTV) services [2].

This work addresses the described problem by proposing a peer-to-peer dissemination mechanism that relies on the cooperation among all participants (as opposed to solutions that assume the availability of an underlying IP-multicast service). The peer-to-peer approach has already proved successfully in circumventing the difficulties faced when attempting to deploy global IP-multicast support [3], [4].

More precisely, this work aims at mechanisms that allow to build multiple trees on top of an unstructured overlay, connecting a data source and a large number of recipients. Tree-based solutions are appealing because they promote an efficient usage of available resources, namely by avoiding the redundancy of approaches such as flooding or gossip. However, in a tree, interior nodes support a much higher load than leaf nodes. Also, the failure of a single interior node is able to break the tree compromising the reliability of the dissemination protocol. These problems can be addressed by using multiple trees, such that each node is interior in just one, or few, trees and a leaf node in the remaining; multiple trees allow to achieve load distribution and also to send (controlled amounts of redundant) information on different trees for fault-tolerance. The introduced redundant data is useful in applications such as live streaming, for instance by leveraging on network coding techniques it is possible to split the original data stream in several slices and send these slices through different trees. These slices might encode enough redundancy such that if a node temporarily misses messages from one of the trees, it is still able to decode the original stream using the remaining slices received from the remaining trees.

This work motivates, describes, and evaluates Thicket, a novel decentralized algorithm to efficiently build and maintain such multiple trees over a single overlay network. As it will become clearer in the following section, Thicket addresses a relatively unexplored region of the design space, by building multiple trees in a decentralized manner, on top of an unstructured overlay. Unstructured peer-to-peer overlays are more robust to system dynamics than structured solutions, such as Distributed Hash Tables (DHTs), as they pose much less constraints of the overlay design space. Thicket has been implemented and has been extensively evaluated using simulations in a P2P overlay with 10,000 nodes and also using a Java prototype.

The remaining of this document is organized as follows. Section II motivates this work by making a survey on competing approaches and by discussing their advantages and limitations. Then, to illustrate the challenges in the proposed design design, in Section III, we demonstrate the limitations of some naive “nuts and bolt’s” approaches to the problem. Thicket is presented and described in detail in Section IV. Section IV briefly describe the implementations of the system that we have developed, and Section VI provides experimental results. Finally, Section VII concludes the paper.

II. RELATED WORK

There are mainly three basic approaches for achieving large-scale information dissemination in peer-to-peer systems: the gossip approach, the tree approach, and the embedded tree approach:

- The gossip approach consists in letting the source select \( f \) peers at random from the system (this is a configuration parameter called \( \text{fanout} \)) and sending the message to them. Upon the reception of a message for the first time, each node simply repeats this procedure. This approach (illustrated by protocols such as [5] or [6]) is simple, highly scalable, and robust. Unfortunately, gossip protocols are not resource efficient, as their robustness derives from a significant amount of redundancy.
- The tree approach consists in having participants coordinating among themselves in order to build an overlay with the topology of a fault-tolerant tree. An example of this approach can be found in [7]. The main advantage of a tree approach is resource efficiency, as the topology avoids unnecessary redundancy in the dissemination process. Unfortunately, a tree is hard to maintain in face of high dynamics, therefore this solution is not efficient for very large systems subject to churn (i.e. constant filiation changes due to concurrent node departure and arrival).

- The embedded tree approach consists of using efficient mechanisms to build an embedded tree over an existing overlay [8], [9]. The overlay maintenance is delegated to some existing protocol.

This work addresses the embedded tree approach, as these solutions typically are able to combine the best features from the pure gossip and the pure tree approaches (as detailed in [8]).

Note that the embedded tree approach can be applied both to structured and unstructured overlays. An example of the former is Scribe [9], that builds trees on top of the Pastry DHT [10]; examples of the later can be found in [8], [11]. Solutions based on unstructured overlays are more appealing as they have the potential to be more robust in face of system dynamics: since unstructured overlays pose less constraints on the topology, they can be repaired faster than structured overlays.

Tree based solutions can be classified in single-tree or multiple-tree solutions. Single tree solutions are naturally simpler but have two main problems: they promote an unbalanced resource usage among peers (nodes that are interior to the tree consume resources to forward data while leaf nodes only receive data); they also suffer from temporary disruptions when one interior node fails and the tree needs to be repaired. Multiple-tree solutions, as the name implies, rely on several trees connecting the same set of participants. Trees are built in such a way that a node is only interior in one or a small subset of all trees and a leaf node in all the remaining. This approach provides load-balancing, as all nodes contribute with their resources (e.g. bandwidth) to forward data. Furthermore, by sending redundant information in some trees (for instance by using network coding techniques[12]), it is possible to achieve higher fault-tolerance: since the failure of a node only disrupts the tree where it acts as an interior node, receivers are still able to operate using the data received from the remaining trees.

Therefore, this work addresses approaches that build multiple-trees. These approaches can be further classified according to the type of algorithm that is used to build the set of trees. Centralized algorithms rely on some specialized nodes, that have a global knowledge of the topology, to build the trees. Note that, even a centralized solution is not trivial, as the problem of optimal tree construction is NP-hard [13].

Centralized approaches have little practical interest for very-large scale systems, as they are not scalable and it is hard to make them fault-tolerant.

Therefore, this work addresses decentralized approaches. The most relevant examples of a decentralized approach are SplitStream [14] and Chunkyspread [15].

SplitStream leverages on a variant of Scribe to build multiple disjoint spanning trees over the Pastry [10] DHT. Similar to this work, the authors strive to build trees in which a node is interior in a single tree. Additionally the authors propose a scheme that allows nodes to control their degree in the tree where they are interior (i.e., controlling the forwarding load of each node) according to their capacities. Unlike this work, the authors rely on a DHT; nodes are interior in a single tree by design, as each tree is rooted in nodes with identifiers having distinct prefixes. Notice that the overhead of maintaining a DHT is far superior than maintaining an unstructured overlay network. Additionally, the unstructured overlay can potentially recover from failures faster than Pastry: in Pastry a crashed node cannot be replaced by any given node, only nodes with the “right” identifier (accordingly to the DHT organization logic) can be employed for this task. Moreover, the scheme employed by the authors to enforce maximum degree on interior nodes may result in several peers becoming disconnected from the tree with a negative impact on the reliability of the data dissemination protocol. SplitStream also requires additional links between peers in addition to the ones provided by Pastry, which results in additional overhead.

Chunkyspread [15] is a protocol that builds and maintains several spanning trees on top of an unstructured overlay network, while trying to limit the load and degree of nodes accordingly to their capacities. However, Chunkyspread mechanism does not attempt to control the number of trees where a node is interior. This results in trees that are not independent among themselves i.e., where nodes can act as an interior node in several trees. This is clearly an undesirable property from the reliability point of view. In fact, we demonstrate in Section VI that independent trees are extremely relevant in scenarios where nodes can fail.

In summary, this work aims at designing a solution that combines the following features: i) It embeds trees in a peer-to-peer overlay, as this offers a good trade-off between efficiency and robustness; ii) is fully decentralized; iii) is able to build multiple-tree that have few interior nodes in common; and iv) can operate on top of unstructured overlays.

Table I illustrates several relevant combinations in the design space for the problem we are addressing, providing some notable examples of solutions for each region. Thicket is the first protocol that not only exploits a relatively unexplored fraction of the design space, that owns several advantages as described above, but also does so while promoting the construction of spanning trees where nodes act as interior mostly in a single tree, contributing to improve the reliability of broadcast schemes.
### III. Some Naïve Approaches

As noted in the previous section, the goal of this work is to design a decentralized algorithm for building \( t \) trees on top of an unstructured overlay. At first sight such a goal may appear to be easy to achieve. In particular, it is tempting to consider an algorithm that is a trivial extension to previous work, namely, the following two alternative solutions appear as natural candidates:

- Since previous work has shown how to build multiple trees on top of a structured overlay, one may consider to use a similar approach on the unstructured overlay. In particular, one could select \( t \) proxies of the root at random (for instance, by doing a random walk from the source node), and then build a different tree rooted at each of these proxies. This approach can also be seen as a simplified version of the Chunkyspread protocol. This approach is named **Naïve Unstructured splitStream**, or simply, NUTS.

- Since previous work has shown how to build a single tree, in a decentralized manner, on top of an unstructured network, one may also consider the simple solution that consists in running such algorithm \( t \) times, i.e., creating \( t \) different unstructured overlays and embedding a different tree over each one of these overlays. The intuition is that the inherent randomization in the construction of the unstructured overlays (and of the embedded trees) would be enough to create trees with enough diversity. This approach is named **Basic multiple OverLay-TreeS**, or simply, BOLTS.

These two basic “nuts and bolts” strategies have been implemented to assess how good they perform in practice. Their resulting performance was analyzed to extract some guidelines for the design of Thicket.

For these experiments, HyParView [18] was used to build the overlay network. HyParView is a protocol for building unstructured overlays that has the feature of balancing both the in- and out-degrees of nodes in the overlay. Therefore, the topology created by HyParView approximates a random regular graph. This is beneficial to the goals of this work, because it makes load balancing easier. For building the trees we have used the Plumtree protocol [8]. Plumtree embeds a tree in topologies such as the ones created by HyParView.

In order to experiment the NUTS approach, a single HyParView overlay was constructed and Plumtree was used to create \( t \) trees rooted at random nodes in the overlay. To experiment the BOLTS strategy \( t \) independent instances of the HyParView overlay were created (by letting nodes join each instance by different random orders) and then embedded a single tree in each of these instances.

### Table I

<table>
<thead>
<tr>
<th>Centralized</th>
<th>Decentralized</th>

<td>CoopNet [17]</td>
</tr>
<tr>
<td>Multiple tree</td>
<td>Scribe [9]</td>
</tr>
<tr>
<td>Bayeux [16]</td>
<td>Splitstream [14]</td>
</tr>
</tbody>
</table>

Both strategies were evaluated by simulating a system composed of 10,000 nodes, and the target of building 5 independent spanning trees (the experimental setup employed will be described in detail in Section VI). For NUTS a single HyParView instance was employed with a node degree of 25. For BOLTS each of the HyParView instances was configured to have a node degree of 5. The fanout value used by the Plumtree instances was set to 5 which is related with the number of neighbors maintained by HyParView for 10,000 nodes [18]. These configurations ensure that each node has an identical number of overlay links in both approaches. Figure 1 plots the percentage of nodes that are interior in 0, 1, 2, 3, 4, and 5 trees.

![Figure 1. K-interior node distribution.](image)

The figure shows that in both strategies only a small fraction of nodes (between 7% and 17%) are interior in a single tree. The majority of nodes in the system are interior in either 2, 3, or 4 trees (with a small fraction being interior in all trees for both strategies). Notice that, for BOLTS, there are some nodes that do not act as interior nodes in any tree (0). Such nodes do not contribute to the data dissemination process, acting always as free riders. This clearly shows that these strategies create (even in steady state) suboptimal configurations, where many nodes are required to forward messages in more than one tree. Additionally, this also indicates that the single failure of a node can disrupt the operation of a significant number, or even all, spanning trees, which clearly compromises the reliability of the data dissemination process.

These results can be explained by the random and uncoordinated nature of tree construction, in which each tree is built in an independent way. In fact, although a large measure of randomness is implicit in the unstructured overlay networks in the BOLTS solution, and the selection of peers is inde-
dependent in NUTS, there is still a significative probability that nodes can be selected to be interior in several trees.

IV. TIKET

A. Architecture

Thicket relies on an unstructured overlay network that implements a reactive peer sampling service and exports a symmetric partial view of the system. The peer sampling service is responsible for notifying the Thicket layer whenever there is a change on the partial view of the node using the NeighborUp(p) and NeighborDown(p) calls.

Thicket operates by employing a gossip-based technique to build divergent spanning trees where most nodes are interior in a single tree and leaf in all other trees. Furthermore, Thicket uses the remaining overlay links for the following purposes: i) ensure complete coverage of all existing trees; ii) detect and recover from tree partitions when nodes fail; iii) ensure that tree heights are kept small, despite the existing dynamics of the system; and finally, iv) the forwarding load of each participant (for all trees where it operates as an interior node) is limited by a protocol parameter named maxLoad.

The maxLoad parameter must be low enough in order to limit the forwarding load imposed to each node, avoiding overloading situations. However, if the chosen value is too low, nodes might be unable to coordinate among themselves in order to generate trees with full coverage (i.e. that connect all nodes). Following epidemic theory maxLoad should be logarithmic with the number of nodes in the system.

Algorithm 1 depicts the data structures maintained by Thicket, as well as its initialization procedure. Each node n in Thicket keeps a set of backupPeersn, with the identifiers of the neighbors that are not being used to receive (or forward) messages in any of the T trees. Initially, all neighbors of n are in this set. Additionally, for each tree t maintained by Thicket, each node n maintains a set t.activePeersn, with the identifiers of the neighbors from which it receives (or forwards to) data messages in t.

Each node n also maintains an announcementsn set, in which it stores control information received from peers that belong to the backupPeersn set. This information is used to detect and recover from tree partitions due to node failures or departures. Later it will be explained in detail how the recovery procedure operates. In order to avoid routing loops, each node also maintains a receivedMsgs set, with identifiers of messages previously delivered and forwarded by a node.

Finally, in order to balance the load of the nodes, i.e., to ensure that most nodes are only interior in a single tree and to limit the message forwarding load imposed to each participant, each node n keeps an estimate of the forwarding load of its neighbors. For this purpose, every time a node s sends a message to another node, it includes a list of values denoting the number of nodes to which s has to forward messages in each tree. Since this information can be encoded efficiently, it is piggybacked to all data and control messages exchanged between neighbors. This allows every node to keep fresh information about the load of its peers without explicitly exchanging messages just for this purpose. Each node n maintains the most recent information received from its neighbor p for each tree t in the variable loadEstimate(p, t)n.

B. Tree Construction

Algorithm 2 depicts a simplified version of the pseudo-code for the tree construction procedure. Some obvious aspects from the pseudo-code have been omitted (for instance the update of the loadEstimate) to improve its readability.

The creation of each tree t is initiated by the source node. To that end, and for each tree t, the source node n selects f nodes at random from the backupPeersn set and moves them to the t.activePeersn set. After this, the source initiates the dissemination of data messages in each tree t, by sending messages to the nodes in t.activePeersn.

All messages are tagged with a unique identifier, muid, composed of the pair (sqnb, t), where sqnb is a sequence number and t the tree identifier. The muids of previously delivered (and forwarded) messages are stored in the receivedMsgs set. Periodically, each node n sends a SUMMARY of this set to all nodes in its backupPeersn set (this messages also include load information used to update loadEstimate).

When a node n receives a data message from s in t, it first checks if the tree has been already created locally. The first message that is received in a given tree t triggers the local tree branching procedure for t. The construction step for an interior node is different from the one executed by the source node. First, n removes s from backupPeersn and adds s to t.activePeersn. Furthermore, if |t.activePeersn| > 1 (i.e., the node is not interior in some other tree t'),

1By reactive, we mean that the contents of partial views maintained by nodes are only updated in reaction to external events such as a peer joining or leaving the system. Symmetric means that the resulting overlay denotes an undirected graph.

2It is assumed that tree identifiers are sequential numbers starting at zero. This list has a size of T. The number in position t represents the forwarding load of that node in tree t (which is the size of t.activePeersn, minus 1).

3For techniques on how to garbage collect obsolete information from this set see for instance [19].
Algorithm 2: Tree Construction

1. upon event Broadcast$(m)$ do
2. tree ← nextTree
3. muid ← (nextSqn(r), tree)
4. if ∃ (muid, p) ∈ tree.activePeers then
5. call SourceTreeBranching(tree)
6. call Forward (m, muid, tree, myself)
7. trigger Deliver$(m)$
8. receivedMsgs ← receivedMsgs ∪ \{muid\}

9. upon event Receive (DATA, m, muid, load, tree, sender) do
10. if muid ∉ receivedMsgs then
11. trigger Deliver$(m)$
12. receivedMsgs ← receivedMsgs ∪ \{muid\}
13. if ∃ (id) ∈ missingFromTree(announcements, tree) : id = muid then
14. cancel Timer(mID)
15. announcements ← removeMuid(muid, announcements)
16. if tree.activePeers = 0 then
17. if sender ∈ backupPeers then
18. tree.activePeers ← tree.activePeers ∪ \{sender\}
19. backupPeers ← backupPeers \{sender\}
20. call treeBranching\(\text{Tree}\)
21. call Balance (mID, mask, tree, sender)
22. else
23. tree.activePeers ← tree.activePeers \{sender\}
24. backupPeers ← backupPeers \{sender\}
25. trigger Send(PRUNE, sender, tree, myself)

26. procedure SourceTreeBranching (tree) do
27. peers ← getRandomPeers(backupPeers, f)
28. foreach p ∈ peers do
29. tree.activePeers ← tree.activePeers ∪ \{p\}
30. backupPeers ← backupPeers \{p\}
31. procedure TreeBranching (tree) do
32. if ∃ t ∈ trees : |t.activePeers| > 1 then
33. peers ← getRandomPeers(backupPeers, f - 1)
34. foreach p ∈ peers do
35. tree.activePeers ← tree.activePeers ∪ \{p\}
36. backupPeers ← backupPeers \{p\}
37. every T seconds do
38. if ∑, Load ≤ maxLoad then
39. summary ← GetNewSummary (receivedMessages)
40. foreach p ∈ backupPeers do
41. trigger send(summary, Load)
42. procedure Forward (m, muid, tree, sender) do
43. foreach p ∈ tree.activePeers: p ≠ sender do
44. trigger Send(DATA, p, m, muid, Load, tree, myself)
45. upon event Receive (PRUNE, load, tree, sender) do
46. tree.activePeers ← tree.activePeers \{sender\}
47. BackupPeers ← BackupPeers \{sender\}

Algorithm 3: Tree Repair

1. upon event Receive (SUMMARY, load, sender) do
2. foreach (muid, p) ∈ SUMMARY do
3. if Timer(t) = t = muid.t then
4. setup Timer(muid.t, timeout)
5. announcements ← announcements ∪ \{muid, sender\}

6. upon event Timer(tree) do
7. (muid, p) ← removeBest(announcements, tree)
8. tree.activePeers ← tree.activePeers \{p\}
9. backupPeers ← backupPeers \{p\}
10. trigger Send(JOINT, p, muid, loadEstimate, Load, tree, myself)

11. upon event Receive (J0INT, muid, load, tree, sender) do
12. if ∑, Load < maxLoad ∧ sender ∈ tree.backupPeers ∧
13. ([tree.activePeers] > 1 ∨ load = Load) then
14. tree.activePeers ← tree.activePeers \{sender\}
15. backupPeers ← backupPeers \{sender\}
16. else
17. trigger Send(PRUNE, sender, Load, tree, myself)
18. procedure Balance (muid, load, tree, sender) do
19. if ∃ (id, p) ∈ announcements : id = tree then
20. newLoad ← IncTreeLoad(loadEstimate, Load)
21. if nInterior(newLoad) < nInterior(load) then
22. trigger Send(J0INT, n, null, loadEstimate, t, Load, myself)
23. trigger Send(PRUNE, sender, Load, tree, myself)

then \(n\) moves at most \(f - 1\) peers from \(backupPeers_n\) to \(t.activePeers_n\). On the other hand, if \(n\) is already an interior node in some other tree, it stops the branching process, becoming a leaf node in \(t\).

The data message is then processed. If the message is not found to be a duplicate (by inspecting the \(receivedMsgs_n\) set), it is forwarded to the nodes in \(t.activePeers_n\) \{s\}. On the other hand, if the received message is a duplicate, the node moves \(s\) from \(t.activePeers_n\) to \(backupPeers_n\) and sends a PRUNE message back to \(s\). Upon receiving the PRUNE message, \(s\) will move \(n\) from \(t.activePeers_n\) to \(backupPeers_n\). This procedure results in the elimination of a redundant link from \(t\) and removes any cycles created by the the gossip mechanism.

By executing this algorithm, nodes become interior in at most one spanning tree. The algorithm also promotes load balancing (as long as the number of data messages sent through each tree is similar). On the other hand, since the mechanism selects random peers for establishing each tree, there is a non negligible probability that some nodes do not become connected to every tree. Such occurrences are addressed by the a tree repair mechanism described in the following section.

C. Tree Repair

The goals of the tree repair mechanism are twofold: i) it is responsible for ensuring that all nodes eventually become connected to all existing spanning trees and, ii) it detects and recovers from tree partitions that might happen due to failure of nodes. This component relies on the SUMMARY messages disseminated periodically by each node. As stated before, SUMMARY messages contain the identifiers of data messages recently added to the \(receivedMsgs\) set. More precisely, each SUMMARY message contains the identifiers of all fresh messages received since the last SUMMARY message was sent by the node.

When a node \(n\) receives a SUMMARY message from another node \(s\), it verifies if all message identifiers are recorded in its \(receivedMsgs_n\) set. If no messages have been missed, the SUMMARY is simply discarded. Otherwise, a tuple \((muid, s)\) is stored in the \(announcements_n\) set for each data message that has not been received yet. Furthermore, for each tree \(t\) where a message has been detected to be missing, a repair timer is initiated: if the missing messages have not been received by the time this timer expires, the node assumes that \(t\) has become disconnected from that tree and takes measures to repair it, as follows.

Consider that node \(n\) has received from a set of nodes \(S\) a SUMMARY message with the \(muid\) of a data message detected to be lost in tree \(t\). Node \(n\) is going to select a single target node \(s_t \in S\) to repair the tree \(t\). The selection
procedure uses the information that nodes keep about the load of their peers (see variable \textit{loadEstimate}(p,t)_n in Section IV-A). Namely, \( s_t \) is selected at random among all peers in \( S \) for which the forwarding load is below a threshold \((\text{maxLoad})\) and that are estimated to be interior nodes in a smaller number of trees, or that are already interior in \( t \) and has not reached a load of \text{maxLoad}.

After selecting \( s_t \), node \( n \) performs the following two steps: \( s_t \) is removed from backupPeers\(_n\) and added to activePeers\(_n\) and a \text{GRAFT} message is sent to \( s_t \). The \text{GRAFT} message includes the current view of \( n \) concerning the load of \( s_t \) (note that \( n \)'s information about \( s_t \) may be outdated, as this information is only propagated when it can be piggybacked on data or control messages).

When \( s_t \) receives a \text{GRAFT} message from \( n \) for tree \( t \), it first checks if \( n \) based its decision on up-to-date values for the load of \( s_t \) (i.e., if the current forwarding load of \( s_t \) matches the information owned by \( n \)) or if, despite eventual inaccuracies in the estimate, \( s_t \) can nevertheless satisfy the request of \( n \) without increasing the number of trees where it is interior nor increasing its current forwarding load to values above \text{maxLoad}. If this is the case, \( s_t \) adds \( n \) to activePeers\(_{s_t}\). Otherwise, \( s_t \) rejects the \text{GRAFT} message by sending back a \text{PRUNE} message to \( n \) (since load information is piggybacked to all messages, this will also update \( n \)'s information on \( s_t \)'s load).

Finally, if \( n \) receives a \text{PRUNE} message back from \( s_t \), \( n \) will move back \( s_t \) from activePeers\(_{s_t}\) to the backupPeers\(_{s_t}\) and attempt to repair \( t \) by picking new targets from the announcements \(_n\) set.

Algorithm 3 depicts a simplified version of this procedure in pseudo-code.

\section*{D. Tree Reconfiguration}

The tree construction and repair mechanisms described above are able to create spanning trees with complete coverage, where a large portion of nodes is interior in a single spanning tree (this happens due to the repair mechanism, as confirmed by experimental results presented in Section VI). This is true in a stable environment (i.e., when there are no joins or leaves in the system). However, multiple executions of the repair mechanism above may lead to configurations where several nodes are interior in more than one tree, which is clearly undesirable.

To circumvent this problem, a reconfiguration procedure was developed that operates as follows: When node \( n \) receives a non-redundant data message \( m \) from a node \( s \) in a tree \( t \) for which it had previously received an announcement from a peer \( a \), it compares the estimated load of \( s \) and \( a \).

If \( \sum_{a} \text{loadEstimate}(s,t)_a > \sum_{a} \text{loadEstimate}(a,t)_n \) and \( n \) can replace the position of \( s \) in tree \( t \) without becoming interior in more trees, node \( n \) attempts to replace the link between \( s \) and \( n \) by a link between \( a \) and \( n \). For this purpose, \( n \) sends a \text{PRUNE} message to \( s \) and a \text{GRAFT} message to \( a \).

Note that the reconfiguration is only performed if the announcement from \( a \) is received before the data message itself from \( s \). This ensures that a reconfiguration contributes to reducing the latency in the tree while avoiding the construction of cycles. Note that, because nodes which forwarding load reaches the \text{maxLoad} threshold are unable to help their peers repairing spanning trees, they cancel the periodic transmission of \text{SUMMARY} messages in this situation.

\section{V. Implementations}

We have developed two implementations of the system. The first implementation was for the PeerSim simulator [20], that we have used to evaluate the performance of the system with a large number of nodes. The second implementation is a Java prototype that permitted the evaluation of Thicket in real-world scenarios, namely using a PlanetLab deployment where Thicket is used to provide a streaming service. In order to make the developed prototype more resilient to failure scenarios, the streaming layer encodes data segments using a Forward Error Correction (FEC) Library. With FEC, a segment composed of \( N \) chunks can be encoded in \( M \) chunks in a way that the reception of \( N \) of the encoded chunks permits the decoding of the original data segment. This is accomplished by introducing redundancy on the encoded chunks. This feature is useful to tolerate temporary disconnections of nodes to a subset of trees. Using FEC, the messages received from remaining trees can still be used to obtain the original data.

\section{VI. Evaluation}

This section reports experimental results obtained using the PeerSim simulator [20]. The complete thesis also includes results for the Java prototype deployment on PlanetLab that are omitted here due to lack of space.

In order to extract comparative figures the performance of the single-tree Plumtree protocol [8] (that serves as baseline to the proposed solution) as well as the “NUTS and BOLTS” alternatives discussed in Section III was also tested. For fairness, all protocols were executed on top of the same unstructured overlay, maintained by the HyParView protocol [18]. HyParView is able to recover from failures as large as 80% of concurrent node failures. Since HyParView uses TCP to maintain connections between overlay neighbors, message losses were not modeled in the system (TCP is also used to detect failures).

All protocols were tested firstly in a stable scenario, where no node failures were induced, and later in faulty scenarios. For faulty scenarios, the reliability of the broadcast process was evaluated under sequential failures of nodes and the reconfiguration capacity of Thicket in a catastrophic scenario, where 40% fail simultaneously. In the following, the experimental setup and the relevant parameters employed in the experiments are described in more detail.

\section*{A. Experimental Setup and Configuration}

Simulations progress in cycles (using the cycle-based engine of the simulator). Each simulation cycle corresponds to 20s. In each cycle the source broadcasts \( T \) messages simultaneously, one message using each of the existing trees
As stated before it is assumed the usage of perfect links, however messages are not delivered to nodes instantly, instead the following delays are considered when routing messages between nodes (these delays are implemented by using the event based engine of the simulator4):

**Sender delay.** It is assumed that each node has a bounded uplink bandwidth. This allows to simulate uplink congestion when nodes are required to send several messages consecutively. In particular each node can transmit 200K bytes/s. Furthermore it is assumed that the payload of data messages had 1250 bytes, while SUMMARY messages have 100 bytes.

**Network delay.** It is assumed that the core of the network introduces additional delays. In detail, in the simulations a message that is transmitted suffers an additional random delay selected uniformly between 100 and 300 ms. These values were selected by taking into consideration round trip time measurements that were performed using the PlanetLab infrastructure5.

All the experiments were conducted using a network of 10,000 nodes and all presented results are an average of 10 independent executions of each experiment. All tested protocols, with the exception of Plumtree, were configured to generate \( T = 5 \) trees. Additionally, Thicket establishes trees using a gossip fanout of \( f = 5 \) and NUTS initiates the eager push set of each spanning tree with 5 random selected overlay neighbors. Thicket, Plumtree, and NUTS operate on top of an unstructured overlay network with a degree of 25, while each of the 5 overlays used by BOLTS has a degree of 5. Furthermore, Thicket was configured to have a maximum forwarding load per node (parameter \( \text{maxLoad} \)) of 7. The timeout employed by protocols when receiving an announcement was set to 2s.

All experiments start with a stabilization period of 10 simulation cycles, which are not taken into account when extracting results. During these cycles, all nodes join the overlay network and the overlay topology stabilizes. After this stabilization period, the broadcasting process starts; this triggers the construction of trees.

### B. Stable Environment

The relevant performance metrics were analyzed for Thicket in a stable environment where no node failures are induced. First, it was evaluated the distribution of nodes accordingly to the number of spanning trees in which they are interior. A value of 0 trees means that such nodes are not interior in any of the trees, i.e. they act as leaves in all trees. The results are depicted in Figure 2(a). Plumtree is plotted in the figure to serve as a baseline for a scenario with a single tree. Note that, with a single tree, only 21% of the nodes are interior nodes, and 79% are leaf nodes.

#### 4The minimum time unit in the system is 1ms.

#### 5The measurements can be found in [http://pdos.csail.mit.edu/~strib/plapp/](http://pdos.csail.mit.edu/~strib/plapp/)

![Figure 2](image_url)
When using both the NUTS and BOLTS strategies, only a small fraction (below 20%) of nodes are interior in a single tree (the plot from Section III is repeated here for the convenience of the reader). Also, for both approaches, there is a small number of nodes that are interior in all 5 trees. As noted before, this motivates the need for some sort of coordination during the tree construction.

In sharp contrast, Thicket has almost all nodes in the system acting as interior nodes in a single tree. A very small fraction (around 1%) serve as interior in 2 trees. This is a side effect of the localized tree repair mechanism, that ensures full coverage of all spanning trees. Still, no node (with the exception of the source node) acts as interior for more than 2 trees. This validates the design of Thicket. Notice also that almost no node is a leaf node in all trees; this contributes to the reliability of the broadcast process (see results below) and ensures a uniform load distribution among participants. Furthermore, it allows to use a much larger fraction of the available resources in the system.

Figure 2(b) depicts the distribution of forwarding load in the system i.e., the distribution of nodes accordingly to the number of messages they must forward across all trees. Because Thicket leverages on its integrated tree construction and maintenance strategy to limit the maximum load imposed to each node, no participant is required to forward more than 7 messages across all trees where it is interior (usually 1 as explained earlier). Additionally, more than 40% of nodes are forwarding the maximum amount of messages, with more than 55% of nodes forwarding a smaller amount of messages. The other solutions however have much more variable loads, with several nodes forwarding more than 10 messages and some with loads above 15 messages. Notice that Thicket is the only protocol where almost no participant has a forwarding load of 0. This is a clear demonstration of the better resource usage and load distribution that characterizes Thicket.

Experiments to evaluate the effect of Thicket in the dissemination of payload messages were also conducted. In particular it was evaluated the maximum number of hops required to deliver a message to all participants, and the maximum latency between the source node and a receiver. Figure 2(c) depicts the number of messages hops required to deliver a data broadcast message to all participants. Plumtree exhibits the highest value. This happens because Plumtree has some difficulties in dealing with variable network latency. This leads to situations where Plumtree triggers message recoveries too early, which increases the number of hops required to deliver a single message to all participants. Plumtree keeps on adjusting the topology during the entire simulation, with the effect of slightly reducing the number of hops, stabilizing at 13 hops.

Thicket presents the best values (11 hops), as the trees created by the protocol are adapted, using the reconfiguration mechanism, to promote trees with lower height, resulting in lower values of last delivery hop (notice that these metrics are related to each other). The BOLTS approach presents a similar result. This happens because the use of several independent overlay networks forces the produced spanning trees (generated with flooding) to use the shortest paths between the source node and all receivers. NUTS has a higher value due to the use of a gossip-based tree construction scheme, that does not guarantee the use of all shortest paths.

Figure 2(d) presents the maximum latency for all protocols. These values are consistent with the last delivery hop values observed. One interesting aspect is that, contrary to all remaining protocols, Thicket presents higher initial values of latency, but these drop quickly in just 5 simulation cycles. This is due to the operation of the tree reconfiguration mechanism.

C. Fault-Tolerance

In this section the performance of Thicket was evaluated in two distinct failure scenarios. In particular the study the impact of sequential node failures in the broadcast reliability when using Thicket, NUTS, and BOLTS. Later, results that illustrate the recovery and reconfiguration capacity of Thicket in a catastrophic scenario that is characterized by a large number of simultaneous node failures are presented. In the experiments the source node and the nodes that serve as root for trees in NUTS never fail.

1) Sequential Node Failures: Now the reliability of the broadcast process in face of sequential node failures is depicted. Here the reliability is considered assuming that the broadcast process leverages in the co-existing spanning trees to introduce redundancy in the disseminated data (for instance by using network coding techniques). Furthermore it is assumed that for each segment of data 5 messages are disseminated, one for each spanning tree, such that if a node is able to receive at least 4 of these messages it is able to reconstruct the data segment, otherwise it is considered that the node misses the reception of this segment. Reliability was defined here as the percentage of correct nodes that are able to reconstruct disseminated data segments.

After an additional stabilization period (5 cycles) the source node was configured to disseminate a data segment per cycle. In each cycle a single node is also forced to fail. The reliability of the broadcast process was measured at the end of each simulation cycle. Furthermore, the node that fails in each cycle was selected using two distinct policies: i) the node that fails is selected at random; ii) the node that fails is selected at random among the nodes that are interior in more trees. Nodes are not allowed to execute the repair mechanism during these simulations, to better capture the resilience of the generated spanning trees. The results for all protocols using the repairing mechanism in this scenario would depict reliability measures close to 100%.

Figure 3 depicts the results for both scenarios. When nodes to fail are selected at random (Figure 3(a)) the reliability of Thicket drops slowly. This happens because most nodes are interior in a single tree. So each failure, affects only nodes bellow the failed one in a single tree, because nodes can reconstruct the data segment even if
they miss messages conveyed by one of the trees, most of them are still able to rebuild data segments as they remain connected to (at least) 4 trees. The reliability drops in a more visible way for both NUTS and BOLTS. This happens because a large majority of nodes are interior in more than a single tree, which results in a single node failure affecting the flow of data in more than a tree.

Note that failing nodes at random may not provide the best metric for reliability. For instance, failing random nodes in a star network only has a noticeable effect in the reliability when the central node fails (this is a single but also the only point of failure). The second experiment is more interesting, as it assesses what happens when “key” nodes crash.

Interestingly, Thicket is extremely robust in face of such a targeted adversary (Figure 3(b)), and its reliability remains constant at 100%. This happens due to the following phenomena: because the forwarding load imposed to each Thicket node is limited, nodes that act as interior in more than a tree are responsible for forwarding messages to a smaller amount of nodes for each tree. Therefore, the effective number of nodes that are affected in each tree is small. Furthermore, because links are never used for more than a tree, these groups of nodes are disjoint, and therefore can still receive messages sent through 4 trees. On the other hand, NUTS and BOLTS are severely affected by this scenario due to the fact that some nodes are interior in all trees, which failure disrupts the flow of data in all trees.

2) Catastrophic Scenario: Now results in face of a large number of simultaneous node failures (in particular 40%) are presented. Note that, with this number of failures, all trees are affected. Therefore, there are no significant advantages of ensuring that nodes are only interior in a single tree. Thus, advantages from a reliability point of view are not expected in this scenario. However, it is worth evaluating if Thicket is able to recover from this amount of failures and if, after recovery, the trees preserve their original properties, namely in terms of nodes that are interior in a single tree and in terms of load distribution. Failures are induced after 100 cycles of message dissemination, to ensure that the spanning trees were already stabilized. Figure 4 summarizes the results.

Figure 4(a) depicts the variation, for each protocol based on multiple trees, of the percentage of nodes that are interior in a single tree. Before the node failures, all protocols exhibit results consistent with the ones presented earlier, for a stable scenario. After the induction of failures the percentage of interior nodes in a single tree drops in BOLTS as result of its recovery procedure, that increases the percentage of nodes acting as interior nodes in multiple trees. NUTS remains unaffected, as the percentage of nodes in this condition is

Figure 3. Experimental results for a catastrophic scenario.

Figure 4. Experimental results for a catastrophic scenario.
only 10% in steady state. Thicket drops to values in the order of 40% after the failures. However the protocol is able to reconfigure itself in only a few simulation cycles.

Figure 4(b) depicts the forwarding load distribution for each protocol. The relevant aspect of this graph is that Thicket is able to regain a similar configuration to the one exhibited in a stable environment. The other protocols configuration remains similar, with nodes exhibiting a wide range of forwarding loads. This is a clear indication that Thicket can regain its properties despite a large number of concurrent failures.

VII. CONCLUSIONS

This work proposes Thicket, the first decentralized algorithm to efficiently build and maintain multiple and independent spanning trees over a single unstructured overlay network. In Thicket most of nodes in the system (almost 100%) act as an interior node in a single spanning tree, and no node is interior in more that 2 trees. This allows to significantly improve the load balancing of participants in tree-based multicast systems, as long as each tree is used to transmit a similar amount of data.

Additionally, Thicket employs a tree reconfiguration procedure that allows it to build trees with limited height. This allows Thicket to present lower, and more stable latency values when compared with other solutions. Additionally, because Thicket operates on top of an unstructured overlay network that is extremely resilient to failures, it can tolerate catastrophic failure scenarios where a large fraction of the nodes in the system fail simultaneously. This is accomplished by exploiting the overlay links that are not used as tree branches.
